

Early Universe Dynamics in Semi-Classical Loop Quantum Cosmology

James E. Lidsey

Astronomy Unit, School of Mathematical Sciences, Queen Mary, University of London, Mile End Road, LONDON, E1 4NS, U.K.

Abstract. Within the framework of loop quantum cosmology, there exists a semi-classical regime where spacetime may be approximated in terms of a continuous manifold, but where the standard Friedmann equations of classical Einstein gravity receive non-perturbative quantum corrections. An approximate, analytical approach to studying cosmic dynamics in this regime is developed for both spatially flat and positively-curved isotropic universes sourced by a self-interacting scalar field. In the former case, a direct correspondence between the classical and semi-classical field equations can be established together with a scale factor duality that directly relates different expanding and contracting universes. Some examples of non-singular, bouncing cosmologies are presented together with a scaling, power-law solution.

1. Introduction

The old idea [1] of bouncing and oscillating universes has attracted renewed interest in recent years. Leading alternatives to inflationary cosmology, such as the pre-big bang scenario (for a review, see, e.g., Ref. [2, 3]) and the cyclic/ekpyrotic model [4, 5, 6] developed from brane dynamics in heterotic M-theory [7, 8, 9, 10], both involve a contracting universe that undergoes a bounce into an expanding phase.

However, the physical process that leads to the bounce in these scenarios is unclear. Indeed, within the context of classical Einstein gravity, a contracting, spatially flat Friedmann–Robertson–Walker (FRW) universe can only undergo a non-singular bounce into an expansionary phase if the null energy condition is violated [11]. Exotic forms of ‘phantom’ matter with negative kinetic energy are often invoked to overcome this shortcoming of the classical theory [12, 13, 14], even though this type of matter leads to negative norm states at the quantum level. Quantum gravitational effects can also lead to non-singular cosmologies. Models inspired by string/M-theory include those where dilatonic loop and higher-order curvature corrections to the tree-level action are introduced [15, 16, 17]. A number of bouncing braneworld scenarios have also been developed [18, 19, 20, 21, 22].

An alternative leading candidate for a non-perturbative and background-independent theory of quantum gravity is loop quantum gravity (LQG). (For reviews, see, e.g., Ref. [23, 24]). This is a canonical quantization of Einstein gravity in terms of Ashtekar variables [25]. Loop quantum cosmology (LQC) is the restriction of LQG to symmetric states. Below a critical value of the scale factor, a_i , the discrete nature of spacetime is important and the Hamiltonian constraint is a difference equation for the wavefunction of the universe [26]. Classical dynamics is recovered when the size of the universe exceeds a second critical value, a_* . Depending on the quantization scheme employed, there is an intermediate ‘semi-classical’ regime, $a_i < a \ll a_*$, where the dynamics of the universe is determined by coupled, ordinary differential equations (ODEs), but where non-perturbative quantum corrections are important. It was recently shown that these corrections generically lead to non-singular bouncing and oscillatory behaviour [27, 28, 29, 30, 31].

In view of the above developments, the purpose of the present work is to develop an approximate analytical framework for studying the dynamics of FRW cosmologies within the context of semi-classical LQC when the universe is sourced by a self-interacting scalar field. In Section 2, we briefly review the main features of LQC, highlighting the quantization ambiguities that lead to important phenomenological consequences. Section 3 develops the analytical framework by identifying the scalar field as a natural dynamical variable of the system. In the case of spatially flat models, a formal correspondence is established between the quantum-corrected Friedmann equations and those of classical Einstein gravity. This enables a ‘scale factor duality’ that relates different backgrounds through an inversion of the scale factor to be identified. This duality can be extended to spatially-curved cosmologies. Classes of non-singular

bouncing cosmologies are found in Section 4, together with a power-law (scaling) solution. We conclude with a discussion in Section 5.

2. Dynamics in Loop Quantum Cosmology

The physical classical variables in isotropic cosmology are the triad component $|p| = a^2$ and the connection component $c = \frac{1}{2}(k - \gamma\dot{a})$, where $\gamma \approx 0.274$ is the Barbero–Immirzi parameter [32, 33] and $k = (0, 1)$ for a (topologically compact) spatially flat or positively-curved universe, respectively[‡]. They form a canonical pair with Poisson bracket $\{c, |p|\} = 8\pi\gamma G/3$ and the dynamics is determined by imposing the Hamiltonian constraint on these variables:

$$\mathcal{H} = -\frac{3}{2\pi G\gamma^2} \left[c(c - k) + (1 + \gamma^2)\frac{k^2}{4} \right] \sqrt{|p|} + \mathcal{H}_\phi = 0 \quad (1)$$

$$\mathcal{H}_\phi = \frac{1}{2}a^{-3}p_\phi^2 + a^3V(\phi), \quad (2)$$

where the matter Hamiltonian, $\mathcal{H}_\phi$, corresponds to that of a minimally coupled scalar field, ϕ , with a self-interaction potential, $V(\phi)$, and canonically conjugate momentum $p_\phi = a^3\dot{\phi}$.

The basic variables in LQG are holonomies along curves in space associated with the connection and triad. For FRW models, the holonomies are given by $h_i = \exp(c\tau_i) = \cos(c/2) + 2\tau_i \sin(c/2)$, where $\tau_i = -i\sigma_i/2 \in \text{SU}(2)$ and σ_i are the Pauli matrices. Quantization of constraint (1) follows by representing the holonomies as operators and promoting the Poisson bracket to a commutator. A primary consequence of LQC is that operators for inverse powers of the spatial volume have eigenvalues that are bounded and do not diverge at zero volume [36]. The matter Hamiltonian (2) contains a divergent factor of a^{-3} . This is quantized by starting from the classical identity $a^{-3} = [3(8\pi\gamma Gl)^{-1}\{c, |p|^l\}]^{3/(2-2l)}$, where l is a constant, and replacing the connection with holonomies [37]:

$$\begin{aligned} a^{-3} &= \left[\frac{1}{4\pi\gamma Gl} \sum_I \text{tr} \left(\tau_I h_I \{h_I^{-1}, a^{2l}\} \right) \right]^{3/(2-2l)} \\ &= \left[\frac{3}{8\pi\gamma Glj(j+1)(2j+1)} \sum_I \text{tr}_j \left(\tau_I h_I \{h_I^{-1}, a^{2l}\} \right) \right]^{3/(2-2l)}, \end{aligned} \quad (3)$$

where the second expression follows because any irreducible $\text{SU}(2)$ representation with spin j may be chosen when computing the trace [38, 39]. In general, j takes half-integer values and $j = 1/2$ corresponds to the fundamental representation. Eq. (3) is a classical identity, but inverse powers of the scale factor are not needed if $0 < l < 1$.

[‡] LQG is a canonical quantization and therefore requires a Hamiltonian formulation of the dynamics. The negatively-curved FRW cosmology represents the isotropic limit of the Bianchi type V universe and, since this is an example of a Bianchi class B model [34], its evolution can not be described in terms of a standard Hamiltonian treatment [35]. We therefore do not consider this model further.

Quantization results in a discrete spectrum for the geometrical density operator, $\hat{d}_{j,l} = a^{-3}$, that is well-defined and can be approximated in terms of a continuous function of the scale factor such that $d_{j,l}(a) \equiv D_l(q)a^{-3}$, where [37, 39]

$$D_l(q) = \left\{ \frac{3}{2l} q^{1-l} \left[(l+2)^{-1} \left((q+1)^{l+2} - |q-1|^{l+2} \right) - \frac{1}{1+l} q \left((q+1)^{l+1} - \text{sgn}(q-1)|q-1|^{l+1} \right) \right] \right\}^{3/(2-2l)} \quad (4)$$

and $q = a^2/a_*^2$, $a_*^2 = a_i^2 j/3$, $a_i = \sqrt{\gamma} \ell_{\text{Pl}}$ and $\ell_{\text{Pl}} = \sqrt{G\hbar}$ is the Planck length. We refer to Eq. (4) as the ‘eigenvalue function’. The discrete nature of spacetime becomes important below the scale a_i . In the limit $a_i < a \ll a_*$, the eigenvalue function asymptotes to

$$D_l(a) \propto (3/(1+l))^{3/(2-2l)} (a/a_*)^{3(2-l)/(1-l)} \quad (5)$$

whereas classical behaviour, corresponding to $d_{j,l} \propto a^{-3}$, is recovered for $a > a_*$. The eigenvalue function is peaked around $a \approx a_*$.

Hence, the geometrical density differs significantly from its classical limit§ below the critical scale a_* . Moreover, the freedom in writing the same classical expression (3) with different values of (j, l) leads to ambiguities at the quantum level that have important cosmological consequences [41, 27, 28, 29, 30, 42, 43]. For $j > 3$, there exists a semi-classical regime ($a_i < a < a_*$), where spacetime may be viewed as a continuum but quantum effects in the density remain important. The dynamics in this regime is determined by replacing the a^{-3} term in the matter Hamiltonian (2) with $d_{j,l}(a)$ [41]:

$$\hat{\mathcal{H}} = -\frac{3}{8\pi\ell_{\text{Pl}}^2} (\dot{a}^2 + k^2) a + \frac{1}{2} d_{j,l} p_\phi^2 + a^3 V = 0, \quad (6)$$

where $p_\phi = d_{j,l}^{-1} \dot{\phi}$.

In the following Section we develop an approximate analytical approach to FRW cosmologies within the context of semi-classical LQC.

3. Scalar Field Dynamics in Loop Quantum Cosmology

The Hamiltonian (6) determines the dynamics via the constraint equation $\hat{\mathcal{H}} = 0$ and the equations of motion $\dot{c} = -\{c, \mathcal{H}\}$ and $\dot{p}_\phi = -\{p_\phi, \mathcal{H}\}$. These take the form

$$H^2 = \frac{8\pi\ell_{\text{Pl}}^2}{3} \left[\frac{1}{2D_l} \dot{\phi}^2 + V \right] - \frac{k^2}{a^2} \quad (7)$$

$$\frac{\ddot{a}}{a} = -\frac{8\pi\ell_{\text{Pl}}^2}{3} \left[\frac{\dot{\phi}^2}{D_l} \left(1 - \frac{1}{4} \frac{d \ln D_l}{d \ln a} \right) - V \right] \quad (8)$$

§ In the spatially flat classical model, the Friedmann equations are invariant under a rescaling of the scale factor, $a \rightarrow Ca$, for some arbitrary constant C , and it is conventional to normalize such that $a = 1$ at the present epoch. The question then arises as to the physical significance of the scale a_* . In the quantum theory, the primary variable is the volume operator and the scale factor arises by taking the cube root. In the quantum theory, therefore, a different normalization for the scale factor is adopted and it is the ratio a_*/a_i that determines the range of the semi-classical regime [40]. The physical scale is not specified until a_i has been evaluated and this can only be done at the quantum level.

$$\ddot{\phi} + 3H \left(1 - \frac{1}{3} \frac{d \ln D_l}{d \ln a} \right) \dot{\phi} + D_l V_\phi = 0, \quad (9)$$

respectively, where $H = \dot{a}/a$ defines the Hubble parameter and a subscript ‘ ϕ ’ denotes differentiation with respect to the scalar field.

In general, the dynamics in the semi-classical regime is complicated due to the non-trivial form of the eigenvalue function (4). An important point, however, is that the transition in going from the semi-classical ($a \ll a_*$) to classical ($a > a_*$) domains is extremely rapid: numerical results indicate that once the eigenvalue function approaches unity it does so very quickly and the asymptotic power-law (5) for the eigenvalue function remains a good approximation until $a \approx a_*$ [43]. We therefore consider the dynamics in the region where Eq. (5) is valid. Such an approximation improves as progressively higher energy scales are considered. It then proves convenient to choose units such that $\ell_{\text{Pl}}^{-2} = 8\pi$ and to define the constant $D_* \equiv [3/(1+l)]^{3/(2-2l)} a_*^{3(l-2)/(1-l)}$. Eqs. (7)–(9) are then equivalent to

$$3H^2 = \frac{1}{2D_*} \frac{\dot{\phi}^2}{a^r} + V - \frac{k^2}{a^2} \quad (10)$$

$$\dot{H} = \frac{q}{2D_*} \frac{\dot{\phi}^2}{a^r} + \frac{k^2}{a^2}, \quad (11)$$

where $r \equiv 3(2-l)/(1-l) > 6$ and $q \equiv (r-6)/6$.

We now proceed to consider spatially flat and positively-curved cosmologies in turn.

3.1. Spatially Flat Cosmologies and Scale Factor Duality

For spatially flat cosmologies, introducing the new set of variables:

$$b \equiv \frac{1}{a^q}, \quad \frac{d}{d\psi} = \frac{D_*^{1/2}}{q} a^{r/2}(\phi) \frac{d}{d\phi}, \quad W[\psi(\phi)] = q^2 V(\phi) \quad (12)$$

maps Eqs. (10) and (11) into the *classical* Einstein field equations sourced by a minimally coupled, self-interacting scalar field, ψ :

$$3\beta^2 = \frac{1}{2} \dot{\psi}^2 + W \quad (13)$$

$$\dot{\beta} = -\frac{1}{2} \dot{\psi}^2, \quad (14)$$

where $\beta \equiv \dot{b}/b = -qH$. The parameters (b, β) may be viewed as the rescaled scale factor and Hubble parameter, respectively.

This formal correspondence between classical and (semi-classical) loop quantum cosmological scenarios has a number of interesting consequences. It represents an ‘ultra-violet/infra-red’ duality, in the sense that the dynamics of expanding or contracting cosmologies in semi-classical LQC can be understood directly by employing methods that have been developed previously in the classical scenario. In particular, since $q > 0$, the correspondence relates a classical expanding cosmology with a contracting LQC solution, and vice-versa.

Moreover, if the scalar field is a monotonically varying function of proper time, Eqs. (13) and (14) can be transformed into the ‘Hamilton–Jacobi’ form [44, 45, 46, 47, 48, 49, 50]:

$$W(\psi) = 3\beta^2 - 2\beta_\psi^2 \quad (15)$$

$$\beta_\psi = -\frac{1}{2}\dot{\psi}, \quad (16)$$

where a subscript denotes differentiation with respect to the rescaled field, ψ , and all variables are viewed as explicit functions of this parameter. It follows from the definition of the β -parameter that

$$b_\psi \beta_\psi = -\frac{1}{2}b(\psi)\beta(\psi) \quad (17)$$

and Eq. (17) may then be integrated to yield the rescaled scale factor in terms of a single quadrature:

$$b(\psi) = \exp \left[-\frac{1}{2} \int^\psi d\psi \frac{\beta}{\beta_\psi} \right]. \quad (18)$$

Expressing the dynamics in this way allows different expanding and contracting backgrounds to be directly related through a duality transformation [51, 52]. To be specific, let us consider a solution to Eqs. (15) and (16) that is parameterized by the functions $[\beta(\psi), b(\psi), W(\psi)]$ and choose as an *ansatz* for a new solution $\tilde{\beta}(\psi) = b(\psi)$. Substituting this *ansatz* into Eq. (18), and noting that the function $b(\psi)$ satisfies Eq. (17), then implies that the new (rescaled) scale factor and potential are given by

$$\tilde{b}(\psi) = \beta(\psi) \quad (19)$$

$$q^2 \tilde{V}(\psi) = 3b^2(\psi) - 2b_\psi^2(\psi), \quad (20)$$

respectively. On the other hand, substituting an *ansatz* of the form $\hat{\beta}(\psi) = 1/b(\psi)$ into Eq. (18) implies that the dual scale factor is given by $\hat{b}(\psi) = 1/\beta(\psi)$ (up to an irrelevant constant of proportionality). It then follows from the definitions (12) that the two new solutions are related by a ‘scale factor duality’ of the form

$$\tilde{a}(\psi) = 1/\hat{a}(\psi), \quad (21)$$

where the corresponding potentials are determined by

$$\tilde{V}(\psi) = \hat{V}(\psi)b^4(\psi). \quad (22)$$

Since this duality relates the scale factor to its inverse, it manifestly pairs an expanding cosmology with a contracting universe. It should be emphasized, however, that the scalar field ψ does not represent the physical field in the LQC setting. The dependence of both the scale factor and potential on the field ϕ is determined from the definition (12) such that $\phi = D_*^{1/2} q^{-1} \int d\psi a^{r/2}(\psi)$.

3.2. Positively-Curved Cosmologies

For positively-curved models, the curvature term in Eq. (10) implies that the redefinitions (12) can not be employed to map the field equations (10) and (11) onto the classical Einstein system. On the other hand, a similar duality to that discussed above can be uncovered. Defining an effective energy density

$$\sigma \equiv \frac{q^2}{2D_*} \frac{\dot{\phi}^2}{a^r} + q^2 V \quad (23)$$

implies that the scalar field equation (9) can be written in the form

$$\dot{\sigma} = -3\beta\dot{\psi}^2. \quad (24)$$

For a monotonically varying field, this implies that

$$\sigma_\psi = -3\beta\dot{\psi} \quad (25)$$

and it follows from the definition of the β -parameter that

$$3\beta^2 = -\frac{b_\psi}{b}\sigma_\psi. \quad (26)$$

Defining a new variable $\chi \equiv b^{-2/q}$ and substituting Eqs. (23) and (26) into Eq. (10) then implies that the Friedmann equation can be expressed in the form

$$\chi_\psi \sigma_\psi - \frac{2}{q} \chi \sigma = -2k^2 q. \quad (27)$$

It may be verified that Eq. (27) reduces to Eq. (17) in the absence of spatial curvature. Since Eq. (27) is invariant under the simultaneous interchange $\chi(\psi) \leftrightarrow \sigma(\psi)$, we may conclude that a given solution parametrized by $[\chi(\psi), \sigma(\psi)]$ can be mapped onto a dual model such that the new scale factor is given by $\tilde{a}(\psi) = \sigma^{1/2}(\psi)$ and the effective energy density is given by $\tilde{\sigma}(\psi) = a^2(\psi)$.

In the following Section we present some exact solutions to Eqs. (10) and (11) for spatially flat cosmologies.

4. Inflating and Bouncing Cosmologies

4.1. Scaling Solution

The correspondence (12)–(14) between classical cosmic dynamics and loop-corrected models implies that a solution to the former can serve as a seed for generating a new solution in LQC. The question of whether such solutions are stable to linear perturbations can also be determined directly from the stability of the seed solution.

For example, one solution of particular importance in conventional cosmology is the power-law model driven by an exponential potential [54]:

$$b = t^{2/\lambda^2}, \quad \psi = \frac{2}{\lambda} \ln t, \quad W = \frac{2(6 - \lambda^2)}{\lambda^4} e^{-\lambda\psi}, \quad (28)$$

where the kinetic and potential energies of the field scale at the same rate. Employing Eq. (12) implies that the corresponding scaling behaviour in LQC is given by

$$\begin{aligned} a &= t^{-2/q\lambda^2}, & \phi &= \frac{2\lambda D_*^{1/2}}{r} t^{-r/q\lambda^2} \\ V &= \frac{2(6-\lambda^2)}{q^2\lambda^4} \left(\frac{r}{2\lambda D_*^{1/2}} \right)^{2q\lambda^2/r} |\phi|^{2q\lambda^2/r}. \end{aligned} \quad (29)$$

Eq. (29) represents a scaling solution in the sense that the ratio of the effective kinetic and potential energies of the field, $\dot{\phi}^2/(a^r V)$, remains constant. It is interesting that when the LQC modifications are significant, the potential is given by a simple power of the field.

Linear perturbations about the classical solution (28) decay with eigenvalue $m = (\lambda^2 - 6)/2$ in an expanding universe [55]. Thus, an expanding (contracting) solution with a positive (negative) potential is always stable for $\lambda^2 < 6$ ($\lambda^2 > 6$). Similar conclusions may therefore be drawn for the LQC solution (29): the stable solutions are represented by a contracting cosmology, where $\lambda^2 < 6$ and the field moves up a positive potential away from $\phi = 0$; or an expanding model, corresponding to a time-reversal of Eq. (29), where $\lambda^2 > 6$, the potential is negative and the field moves towards $\phi = 0$. This latter solution represents a superinflationary cosmology. (Note that although the solution becomes singular as $t \rightarrow 0^-$, the approximation (5) inevitably breaks down before this point is attained).

4.2. Bouncing Cosmologies

Eq. (11) implies that $\ddot{a} > 0$ and it follows that a necessary and sufficient condition for a contracting spatially flat universe to undergo a non-singular bounce is that the first derivative of the Hubble parameter should remain finite at the point where the sign of H changes^{||}. Moreover, the potential of the field must be negative at the bounce and, consequently, the scalar field must be a monotonically varying function of proper time. The framework outlined in Section 3.1 is therefore ideally suited to determining the dynamics of spatially flat, bouncing cosmologies. It proves convenient to express Eqs. (15)–(16) in terms of the original variables such that

$$V = 3H^2 - \frac{2D_*}{q^2} a^r H_\phi^2 \quad (30)$$

$$H_\phi = \frac{q}{2D_*} \frac{\dot{\phi}}{a^r}. \quad (31)$$

The scale factor is then given by

$$a^r(\phi) = C + \frac{qr}{2D_*} \int^\phi d\phi \frac{H}{H_\phi}, \quad (32)$$

^{||} We assume implicitly that the scale factor is positive-definite.

where C is a constant of integration, and the time dependence of the scalar field follows by integrating Eq. (31):

$$t = \frac{q}{2D_*} \int^\phi \frac{d\phi}{H_\phi(\phi)a^r(\phi)}. \quad (33)$$

Eqs. (30)–(33) imply that the dynamics of semi-classical LQC is determined once the Hubble parameter, $H(\phi)$, has been specified as a function of the scalar field. The potential and scale factor follow immediately from Eqs. (30) and (32) and the corresponding time-dependences of the scale factor and scalar field can then be deduced after integrating Eq. (33) and inverting the result.

In view of this, we now proceed to derive two classes of bouncing models by specifying the dependence of the Hubble parameter on the value of the scalar field. We begin by considering a Hubble parameter of the form

$$H(\phi) = B\phi^n, \quad (34)$$

where B and n are arbitrary constants. Integrating Eq. (32) implies that the scale factor is given by

$$a^r(\phi) = C + \frac{qr}{4nD_*} \phi^2 \quad (35)$$

and Eq. (30) implies that the potential has the form

$$V(\phi) = -\frac{2CB^2D_*n^2}{q^2} \phi^{2n-2} - \left(\frac{3B^2}{q} \right) \left[1 + \frac{r}{6}(n-1) \right] \phi^{2n}. \quad (36)$$

For the case where the integration constant $C = 0$, it can be verified that Eqs. (34) and (35) correspond to the scaling solution (29) discussed above. Eq. (33) is also integrable for the case $n = 1$ and $C \neq 0$ and the solution in this case is given by

$$\begin{aligned} a(\phi) &= C^{1/r} \sec^{2/r} \left(\sqrt{\frac{CB^2D_*r}{q}} t \right) \\ \phi(t) &= \left(\frac{4CD_*}{qr} \right)^{1/2} \tan \left(\sqrt{\frac{CB^2D_*r}{q}} t \right) \\ V(\phi) &= -\frac{2B^2CD_*}{q^2} - \frac{3B^2}{q} \phi^2, \end{aligned} \quad (37)$$

where it is understood implicitly that $-\pi/2 < t < \pi/2$. The potential (37) has a simple quadratic dependence on the scalar field, and differs from the scaling potential only by a negative constant, $-2B^2CD_*/q^2$. However, the effect of this constant shift in value is significant: the solution now represents a cosmology that contracts to a minimum radius at $t = 0$, at which point the field reaches the maximum of its potential, and then bounces into an expanding phase as the field rolls down the other side of the potential. The integration constant C determines the shift in the potential and represents the minimal value of the scale factor.

In principle, models with more complicated potentials can be derived in a straightforward manner by specifying $n \neq 1$, although it is not always possible to integrate and invert Eq. (33) in these cases.

Finally, a second class of model can be found that represents a universe that bounces into an asymptotic phase of exponential (de Sitter) expansion. It is given by

$$H = \frac{A\phi}{[8 + qr\phi^2]^{1/2}}, \quad V = \frac{A^2}{q^2} \left(\frac{3q^2\phi^2 - 2}{qr\phi^2 + 8} \right)$$

$$a(t) = \frac{1}{D_*^{1/r}} \cosh^{4/r} \left(\sqrt{\frac{rA^2}{16q}} t \right), \quad \phi(t) = \sqrt{\frac{8}{qr}} \sinh \left(\sqrt{\frac{rA^2}{16q}} t \right), \quad (38)$$

where A is an arbitrary positive constant and the constant of integration in Eq. (32) is chosen to be $C = 1/D_*$. The potential asymptotes to a positive constant for large $|\phi|$ and has a single minimum at $\phi = 0$. The universe bounces into an expanding phase as the field passes through this minimum.

5. Conclusion

In this paper, we have considered expanding and bouncing universes within the context of semi-classical loop quantum cosmology, corresponding to the regime where the cosmic dynamics is determined by quantum-modified Friedmann equations. The analytic approach developed here compliments previous numerical and qualitative studies [27, 28, 29, 30, 42, 43] and applies in the limit where the eigenvalue function of the inverse volume operator has a power-law dependence on the scale factor.

Such a study is important as it yields insight into the generic nature of these models, as well as providing a framework for classifying the different types of possible behaviour that may arise. In particular, the modified evolution equations for spatially flat models can be recast, after appropriate field redefinitions, into the classical Einstein equations for a minimally coupled, self-interacting scalar field. A similar correspondence between standard relativistic cosmology and the high-energy limit of the Randall-Sundrum type II braneworld [56] has also been identified recently [57, 58, 59, 60] and it would be interesting to explore possible relationships between these apparently unrelated scenarios further.

Within the LQC framework, such a correspondence is intriguing because it indicates that the dynamics at ultra-high energy scales, where the universe is just emerging from a truly discrete quantum phase described by a difference equation, can be analyzed in terms of low-energy classical models, and vice-versa. By expressing physical parameters such as the scale factor and Hubble parameter as functions of the scalar field, we identified a form-invariance transformation [51, 52, 53] that inverts the scale factor of the universe. This scale factor duality between two different backgrounds directly relates expanding and contracting models and can be extended to the spatially-curved models.

The scale factor duality considered above is different to that arising in quantum cosmological models derived from lowest-order string effective actions [61, 62, 63, 64, 65]. In this latter class of models, the duality may be viewed as a discrete subgroup of a global $O(d, d)$ symmetry of the effective action that arises after toroidal compactification over

d spatial dimensions if the dilaton potential has a suitable functional form [66]. Thus, the duality of string quantum cosmology relates different backgrounds arising from the same fundamental Lagrangian. In contrast, however, the scale factor duality of LQC relates solutions arising from inequivalent actions, i.e., the transformation (21)–(22) acts between scalar fields with different self-interaction potentials. Moreover, the scale factor duality of LQC becomes apparent when the field equations are expressed as functions of an effective scalar field defined by the condition (12), whereas the $O(d, d)$ symmetry of string cosmology is only apparent when the degrees of freedom are viewed explicitly as functions of cosmic time [66]. A further difference between the two approaches is that the field is minimally coupled to Einstein gravity in LQC, whereas the dilaton is non-minimally coupled to gravity. In view of the (classical) conformal equivalence between scalar-tensor and Einstein theories of gravity, therefore, it would be interesting to investigate the LQC approach within the context of scalar-tensor gravity models such as the Brans–Dicke theory. Such an approach could yield further insight into the similarities and differences between the LQC and string quantum cosmology frameworks.

Finally, we presented simple models that exhibit scaling and bouncing behaviour in the semi-classical regime. One of the principle motivations for developing non-singular bouncing cosmologies is that they provide an alternative to the inflationary scenario for the formation of large-scale structure in the universe. In principle, density perturbations on scales larger than the Hubble radius at the epoch of decoupling can be generated during a phase of decelerated contraction [67, 68, 13, 69]. Since a number of issues regarding the propagation of perturbations through the bounce presently remain unresolved [70, 71, 72, 73], it is important to develop non-singular bouncing models as these can provide a solvable framework for analyzing the evolution of perturbations. Moreover, the scaling (power-law) solution has played a central role in the standard inflationary scenario and represents one of the few known cosmologies where the density perturbation spectrum can be calculated without invoking the slow-roll approximation [54, 74]. It would be interesting to investigate whether the scaling solution derived above plays a similar role in determining the evolution of density perturbations generated in the semi-classical LQC regime. Ultimately, this could lead to important phenomenological constraints on LQC inflationary models.

Acknowledgments

We thank P. Singh for helpful discussions.
